- Results
- Conclusions

# What is it?

The TSMP is a

- medium access and
- networking

protocol that provides

- reliable,
- low power and
- secure

communication in a managed wireless mesh network!

Also...

- scalable,
- flexible,
- low-maintenance,
- self-organizing,
- self-healing,
- wow!

# Background Check

Presented on **DSN 2008**, Orlando, Florida, USA

Kristofer S. J. Pister, Lance Doherty

# Management

Yup, **managed** network.

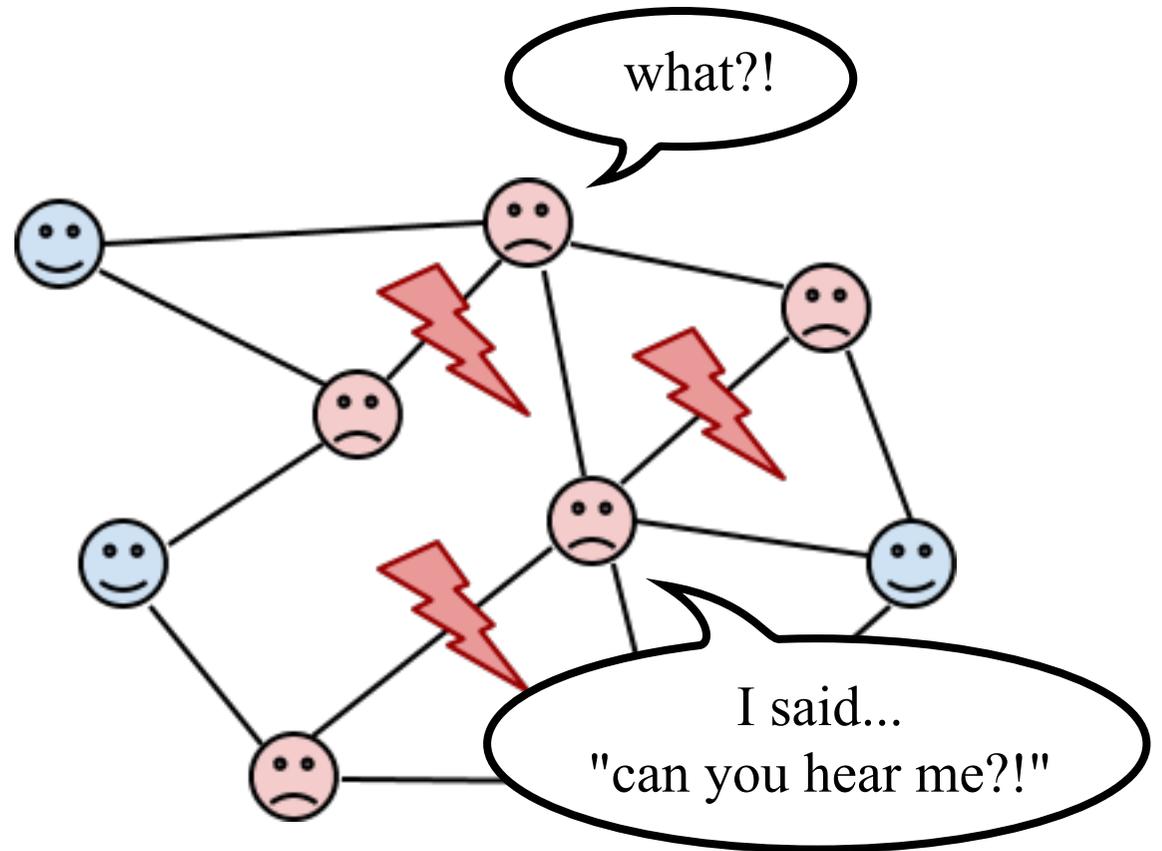

TSMP relies on the existence of a centralized controller to coordinate the communication schedule of the network. This guy is called the **manager**.

Real deployments show that **scalability** and **robustness** are no big issues.

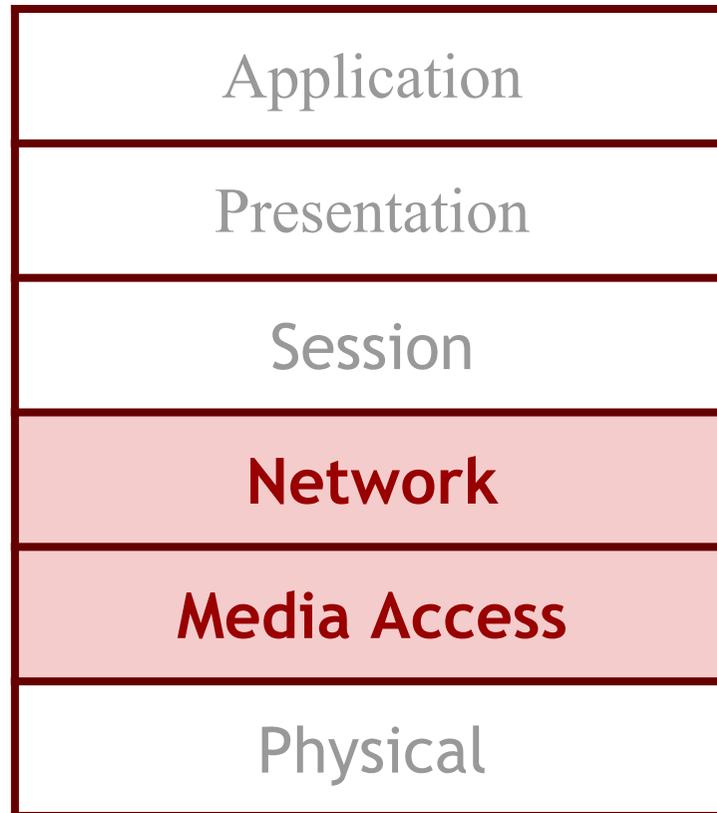

But the **limit** is somewhere.

# Wireless Challenges

- Interference
- Blocked paths
- Node loss

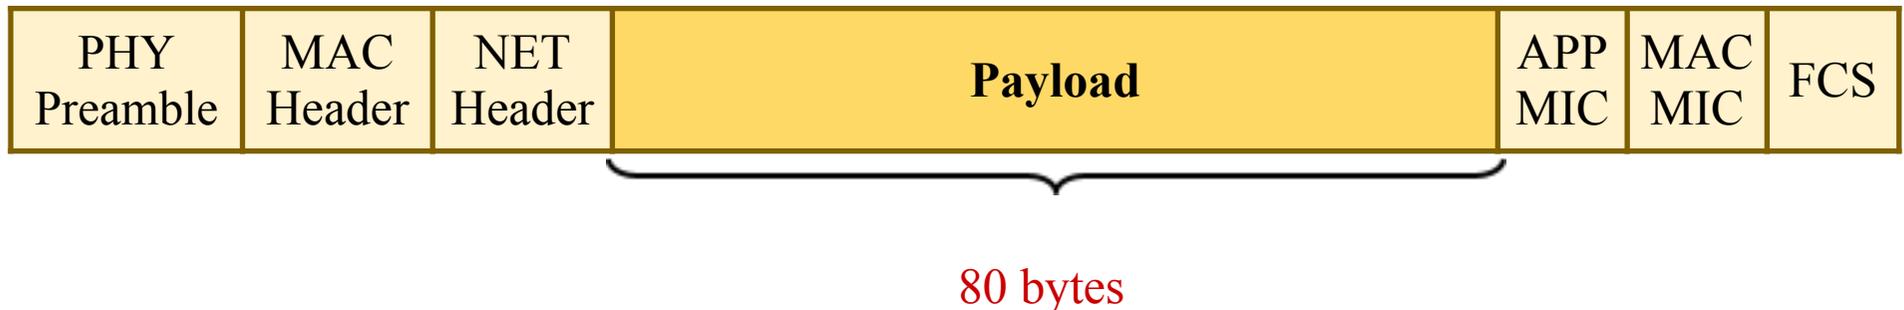

# TSMP is all about...

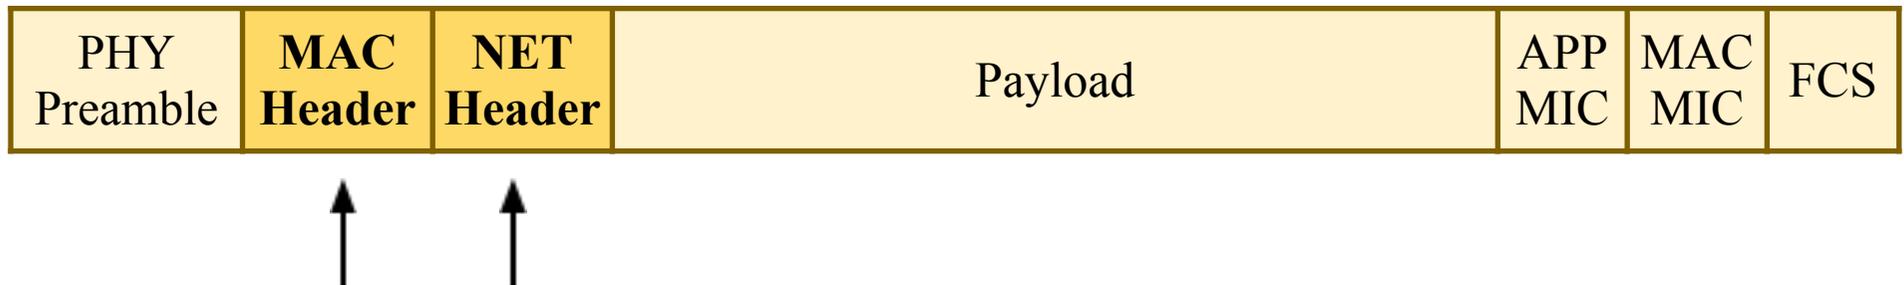

# Packet format

In the **802.15.4** wireless standard,

- packet size is **127 bytes**,
- of which **47 bytes** are reserved by TSMP,
- leaving **80 bytes** as payload.

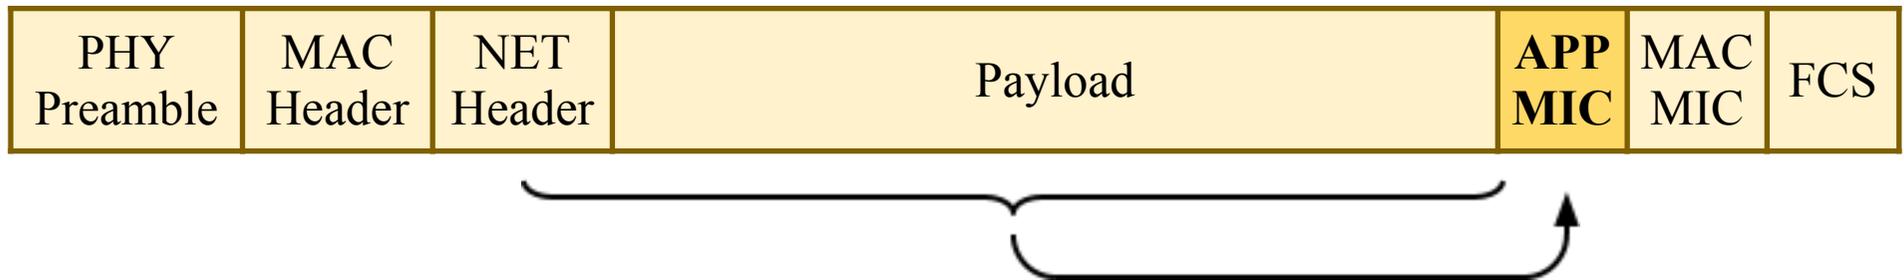

# Packet format

The **NET header** contains information on End-to-End **addressing** and **routing**.

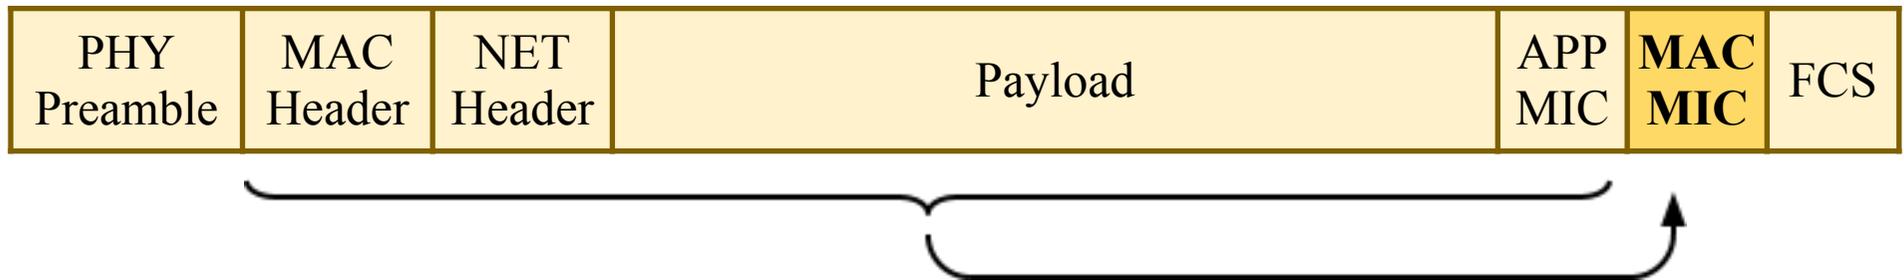

The **MAC header** contains information about Per-hop **addressing** and **timing**.

# Packet format

TSMP first constructs a Message Integrity Code of both the application layer **payload** and a **nonce** that resides in the Network Header.

# Packet format

Then, the MAC Message Integrity Code is build from both **headers**, the **payload** and the **previous MIC**.

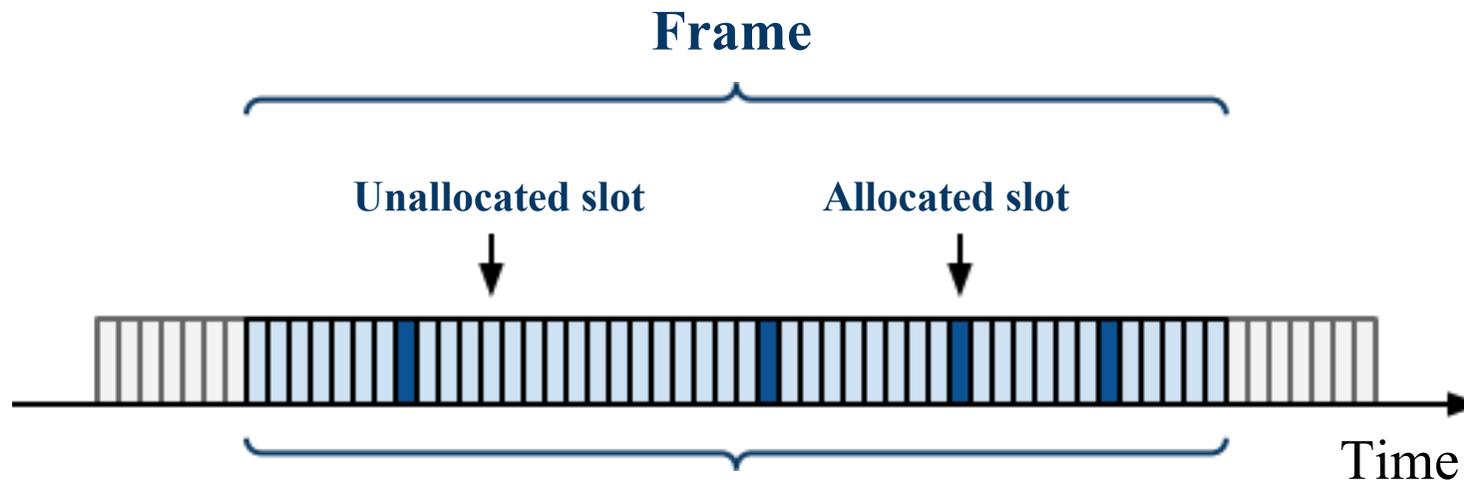

**Nice packet!**

# 1. TDMA

Time Division Multiple Access

**Reduces interference** from other TSMP nodes by scheduling communication in precise instances of time.

# 1. TDMA

Time Division Multiple Access

**sync!**

# Synchronization

Rule #1: **Do it well**

Sync  
frequency

VS.

Energy  
consumption

# Synchronization

Rule #2: **Do it fast**

Time spent  
sync'ing

VS.

Time gained  
by sync'ing

# TSMP Synchronization

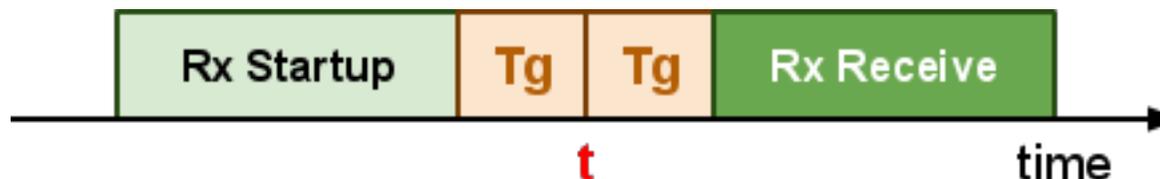

Time sync information is shared by piggybacking it with every ACK packet!

# TSMP Synchronization

A node expects a packet at instant  $t$ .

Establish  $T_g$  seconds as the worst-case clock skew between any two nodes.

Guard time  $\rightarrow 2T_g$

# TSMP Synchronization

Given a guard time  $T_g$ , how often ( $T_{\text{sync}}$ ) need two nodes to synchronize?

# TSMP Synchronization

$$\varepsilon \leftarrow r_2 - r_1$$

Once synced at  $t_0$ , synced again at  $t$ , with synch error  $\delta$ .

Worst difference in shared time is  $\Delta t_{\max} = \varepsilon (t - t_0) + \delta$ .

$$\Delta t_{\max} < T_g$$

$$(t - t_0)_{\max} = T_{\text{sync}} < (T_g - \delta) / \varepsilon !!!$$

# TSMP Synchronization

$$T_{\text{sync}} < ( T_g - \delta ) / \epsilon$$

For example, define a guard time of  $\pm 1\text{ms}$ ,  $50\mu\text{s}$  of synch error and  $\pm 10\text{ppm}$  of rate difference between two nodes...

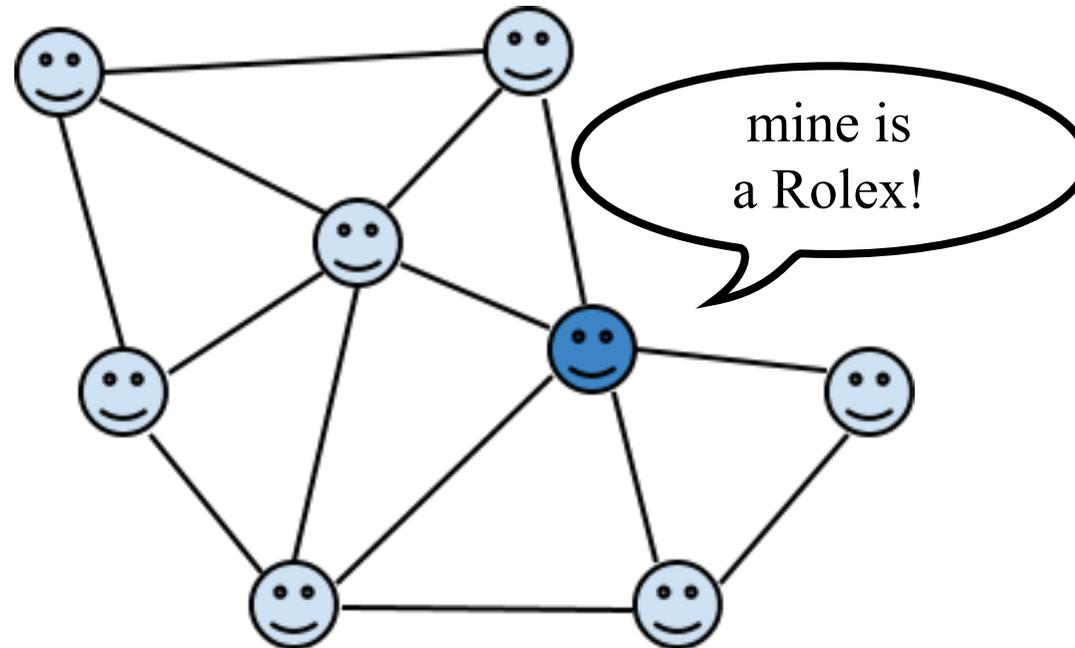

... they need to be synchronized every **48s!**

# TSMP Synchronization

What if they're not?

**brb...**

# TSMP Synchronization

Time is propagated from a single time-master...

# TSMP Synchronization

What if they're not?

Parents can broadcast **beacon** packets.

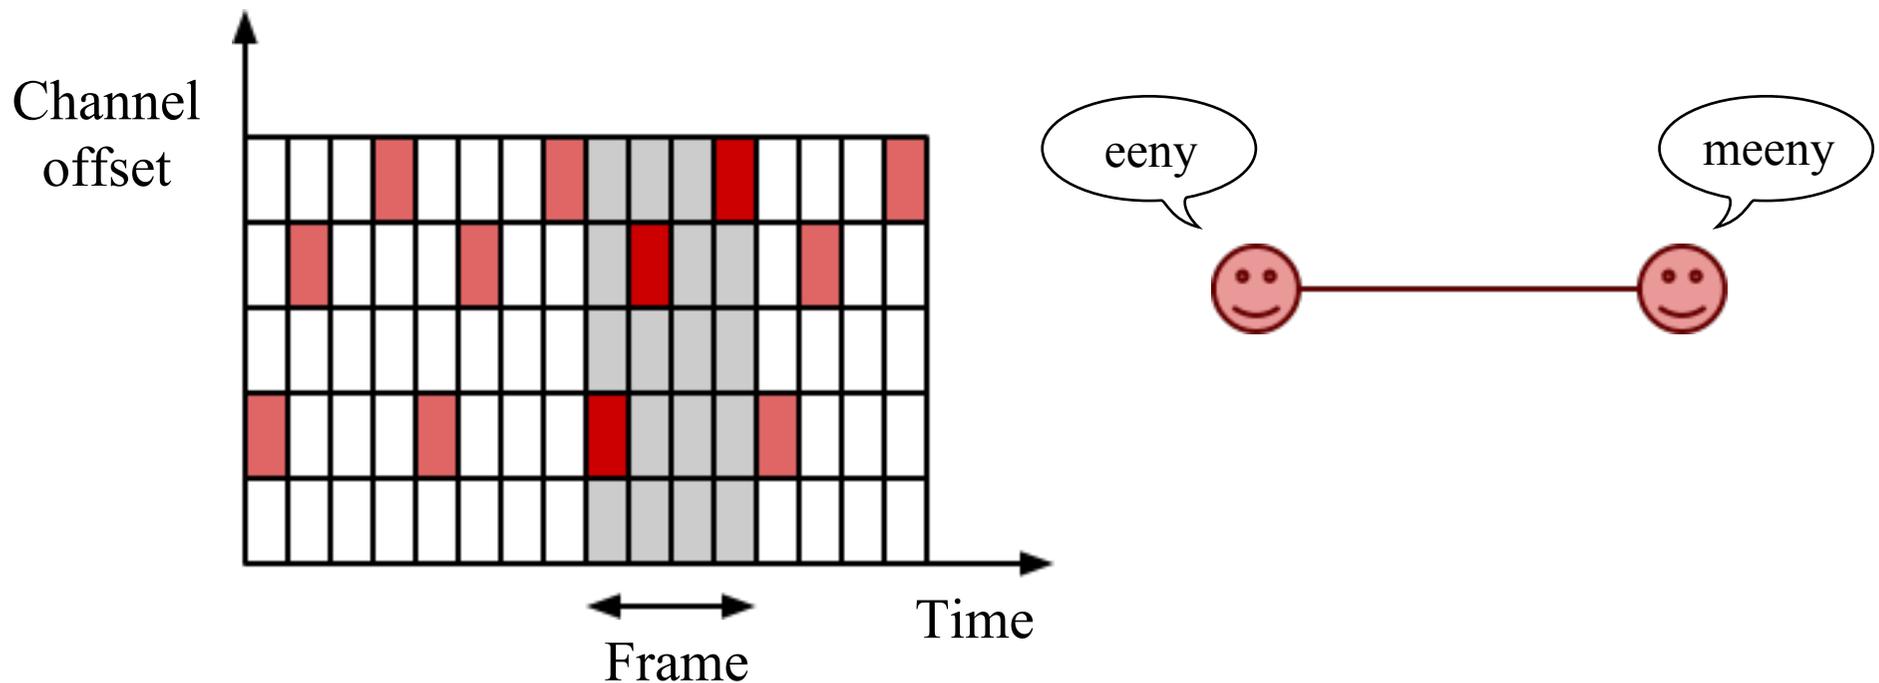

Children can send **keepalive** packets.

Ultimately how often your nodes will sync depends on the type of network installed: **periodic data-gathering**, **alert-based**, et al.

## 2. FHSS

Frequency-hopping Spread Spectrum

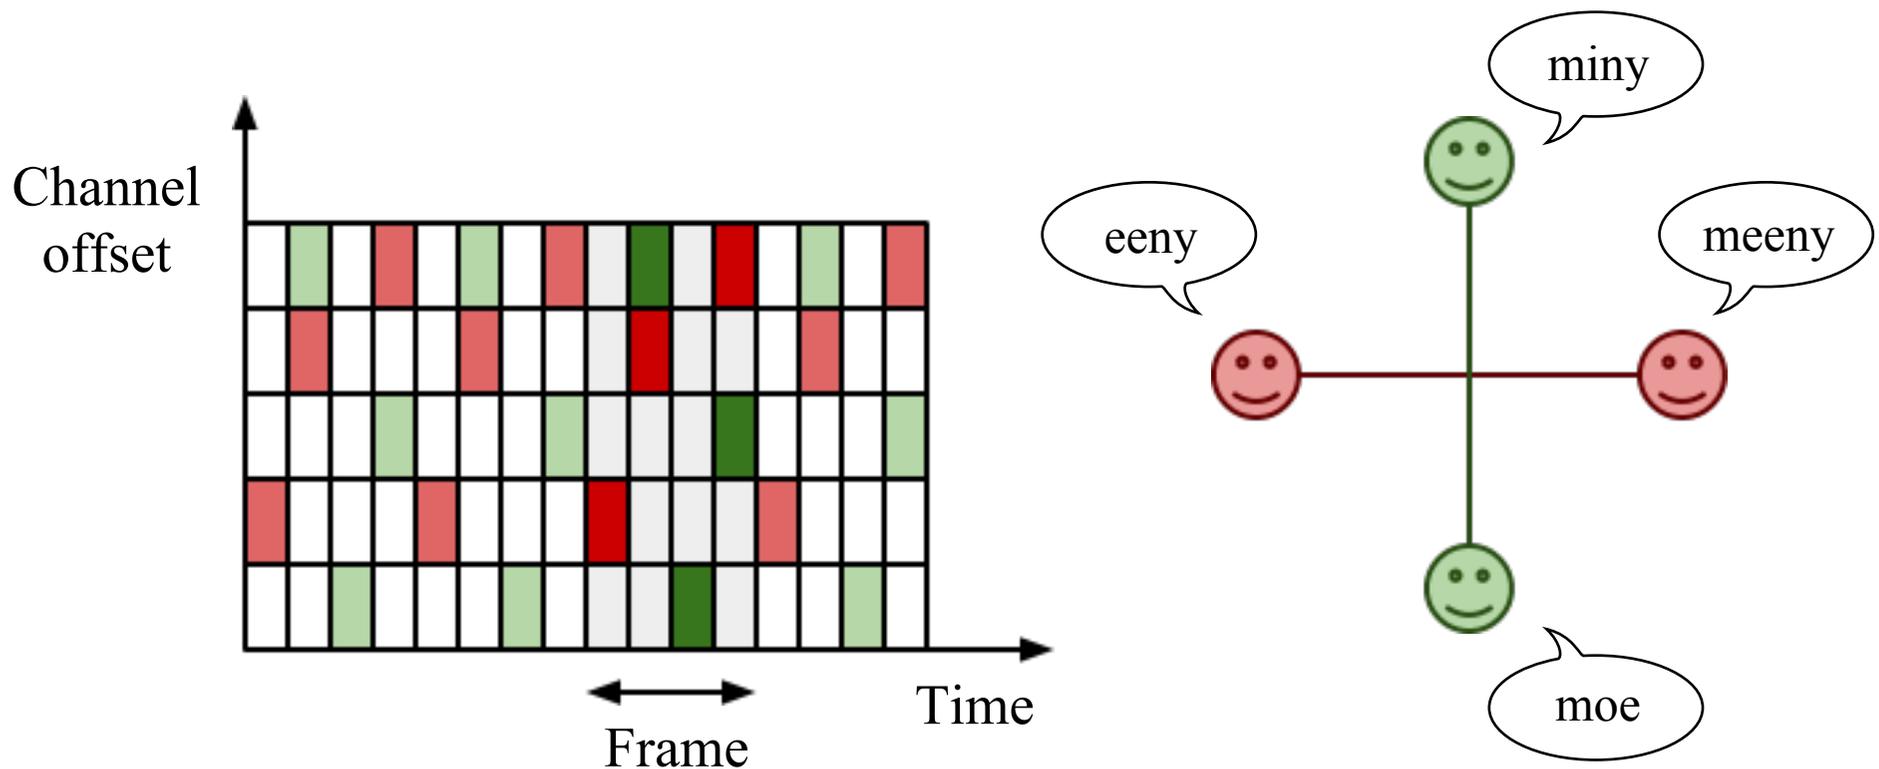

**Reduces interference** probability by spreading the signal over several channels, using different frequencies.

## 2. FHSS

Frequency-hopping Spread Spectrum

Also, it **increases bandwidth** in the order of the number of channels!

# TSMP Channel Hopping

$$\text{Channel} = \text{Lookup}[(\text{ASN} + \text{Offset}) \% \#Channels]$$

**Lookup** is a randomly sorted loop-up-table with values ranging from 0 to  $\#Channels-1$ .

**ASN** stands for the **Absolute Slot Number** since the beginning of the network.

Communication happens in **links** which are characterized by their **offsets** (**more on links later**).

# Bandwidth

Using the **802.15.4** wireless, with **16 channels**,  
**60 time slots per second** and **80 bytes of payload**,

theoretically we get

$$16 * 60 * 80 = 76.8 \text{ KB/second}$$

of **application level bandwidth**.

# Network Maintenance

But, do remember that TSMP reserves time slots for

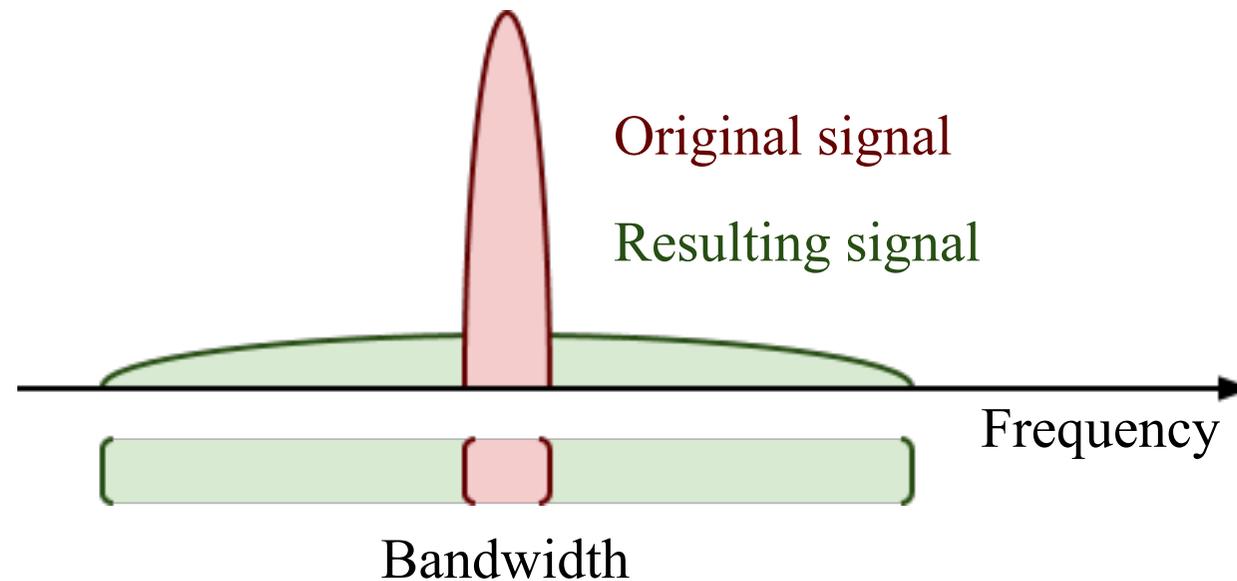

- network configuration,
- neighbor discovery and
- join requests listening.

This will come in handy in a sec...

### 3. DSSS

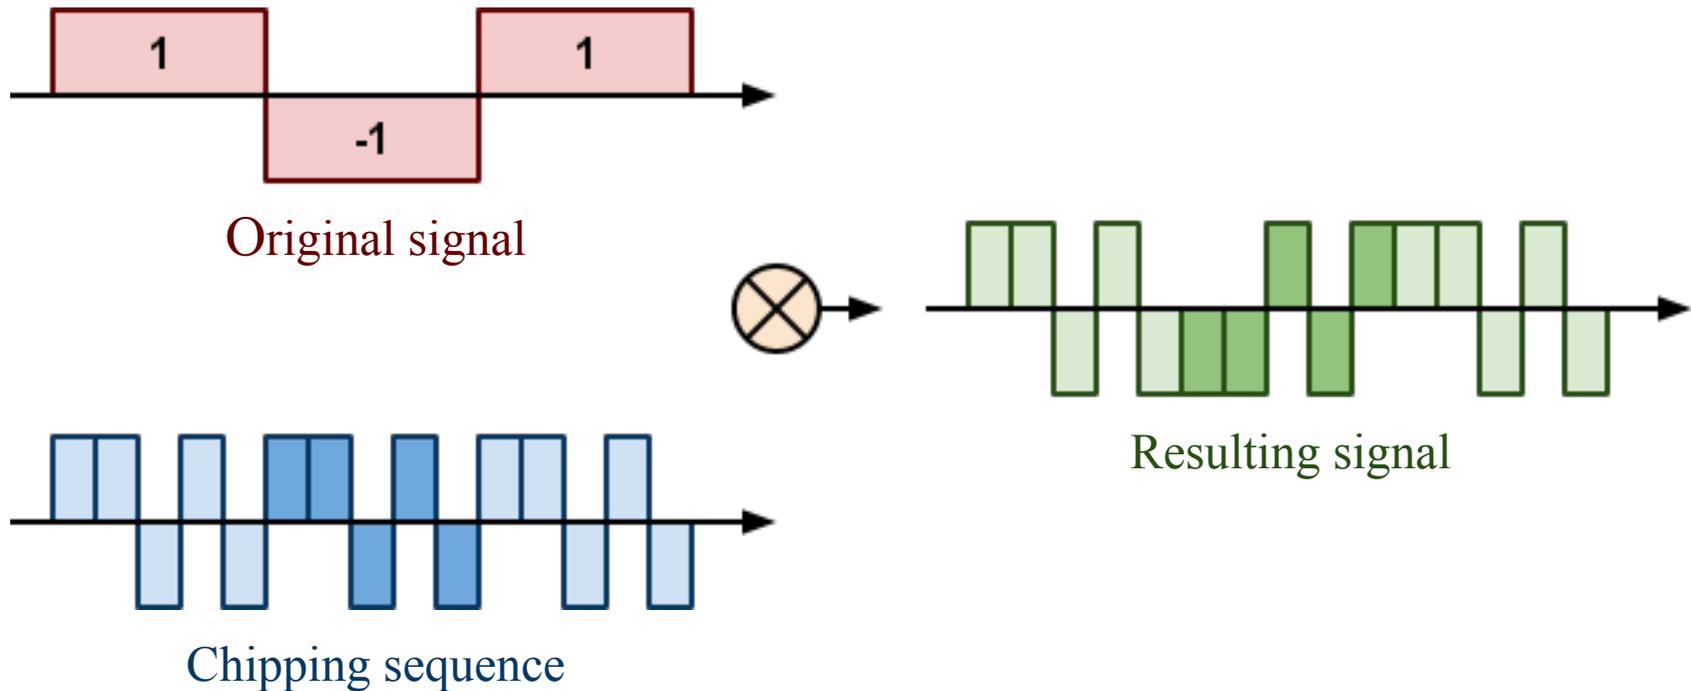

Direct-sequence Spread Spectrum

**Reduces interference** probability by spreading the signal over more bandwidth.

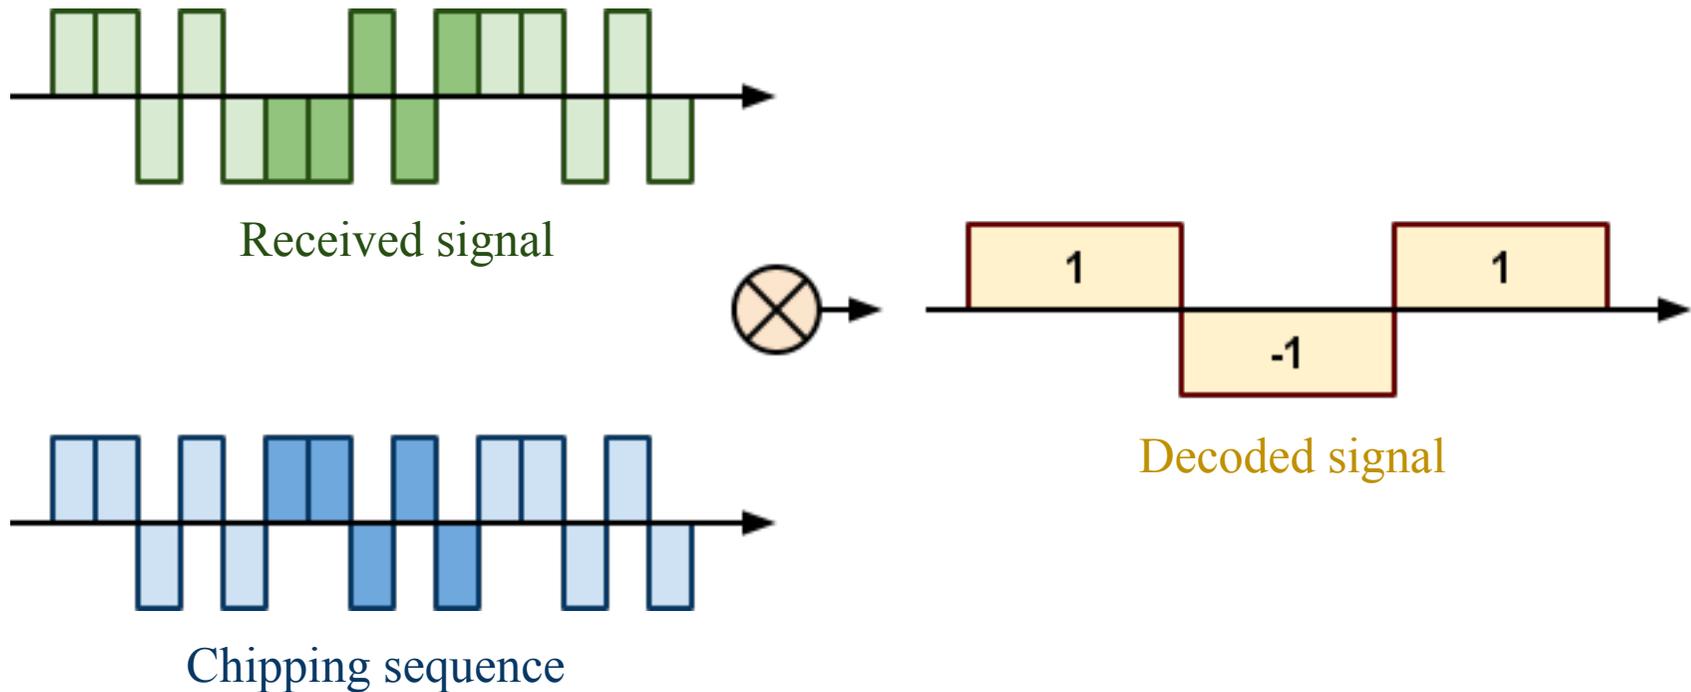

# 3. DSSS

Direct-sequence Spread Spectrum

# 3. DSSS

Direct-sequence Spread Spectrum

# Extra: Link-Layer ACKs

One more thing...

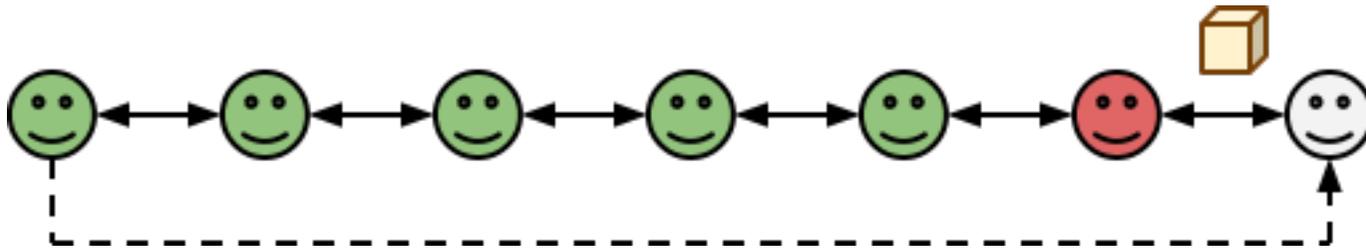

ACKs are generated on the Link layer!

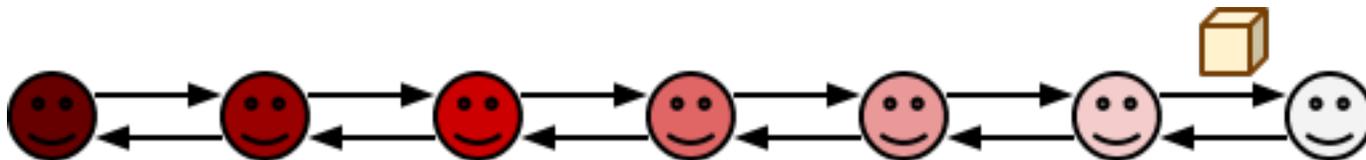

After **FCS** and **MAC MIC** verification,  
a **positive** or **negative** ACK is sent back accordingly.

# Extra: Link-Layer ACKs

Provides **reliability** without too much overhead by doing this:

instead of this:

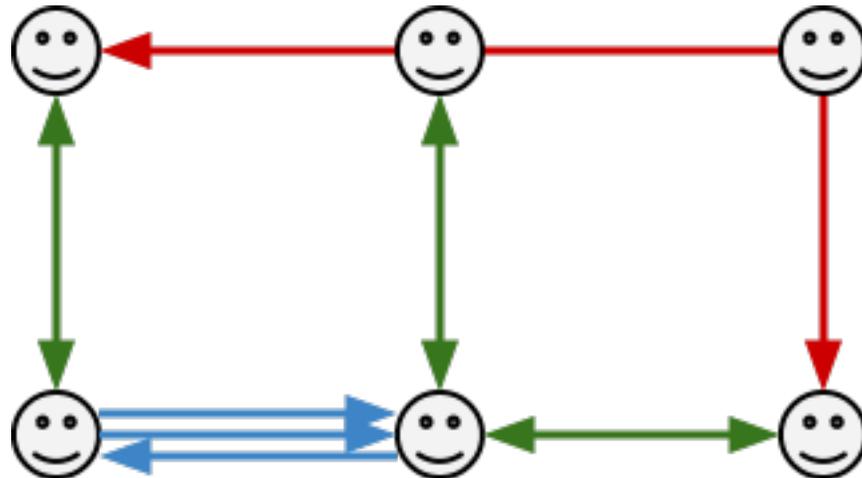

# NET

# Definitions

Paths, routes, links, oh my!

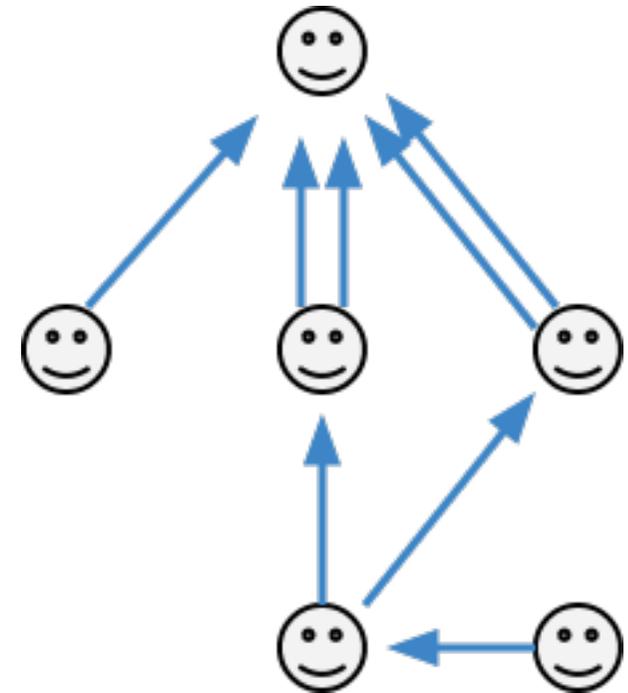

**Links** are requested to the manager and with more **links** comes more bandwidth!

# Graph Routing

Link allocation creates graphs of data flow!

Multiple communication graphs in the same network are possible.

# Definitions

A **network** is a set of nodes that share a **network ID**, typically rooted by a **gateway node** that is both

- the **timing master** and
- responsible for relaying **network configuration**.

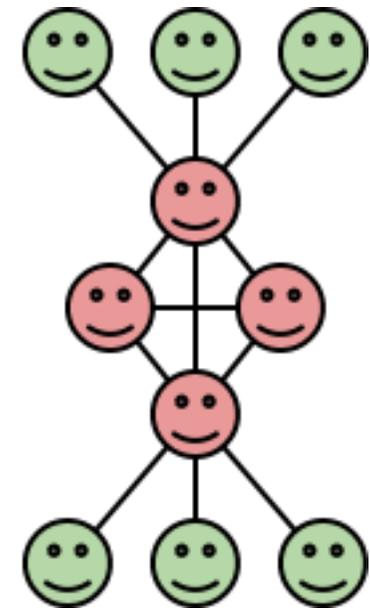

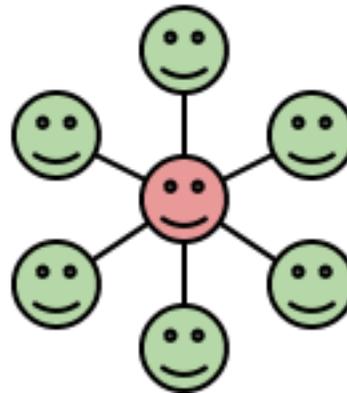

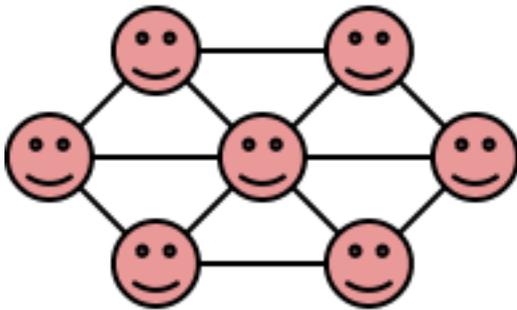

But: *"all nodes are created equal"*.

# Mesh Routing

A **router** node might become an **end node**, throughout the existence of the network, and vice-versa.

Flexibility, extendability, scalability.

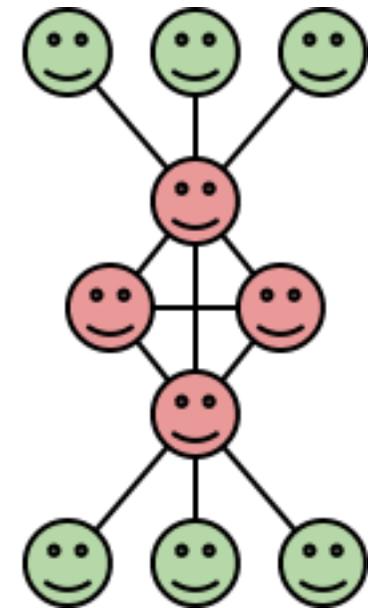

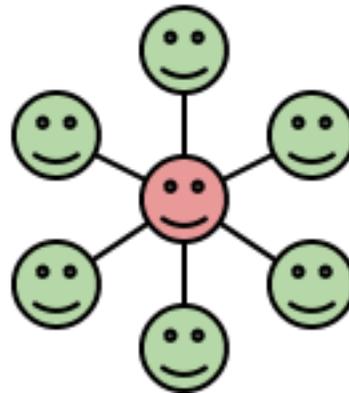

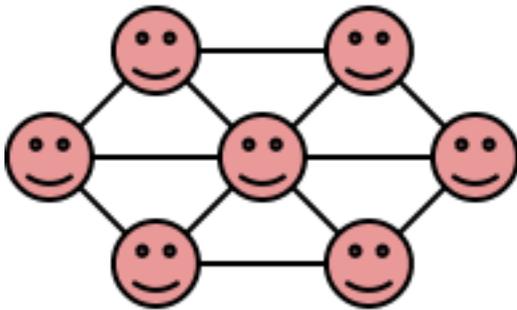

Configurability too!

# Mesh Routing

TSMP provides **fully redundant mesh routing** and relies on both

- automatic node joining and
- constant network healing.

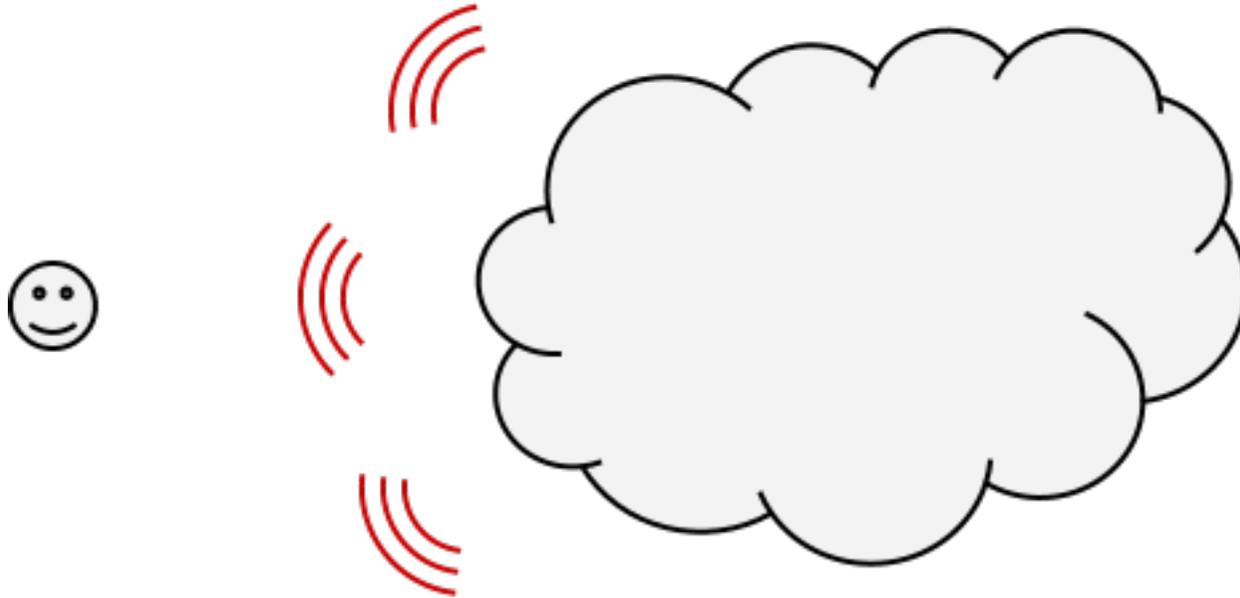

# Fully Redundant Routing

*"Redundancy by diversity"*

**Spacial diversity** by maintaining **multiple parent nodes** and requesting **links** that connect to them.

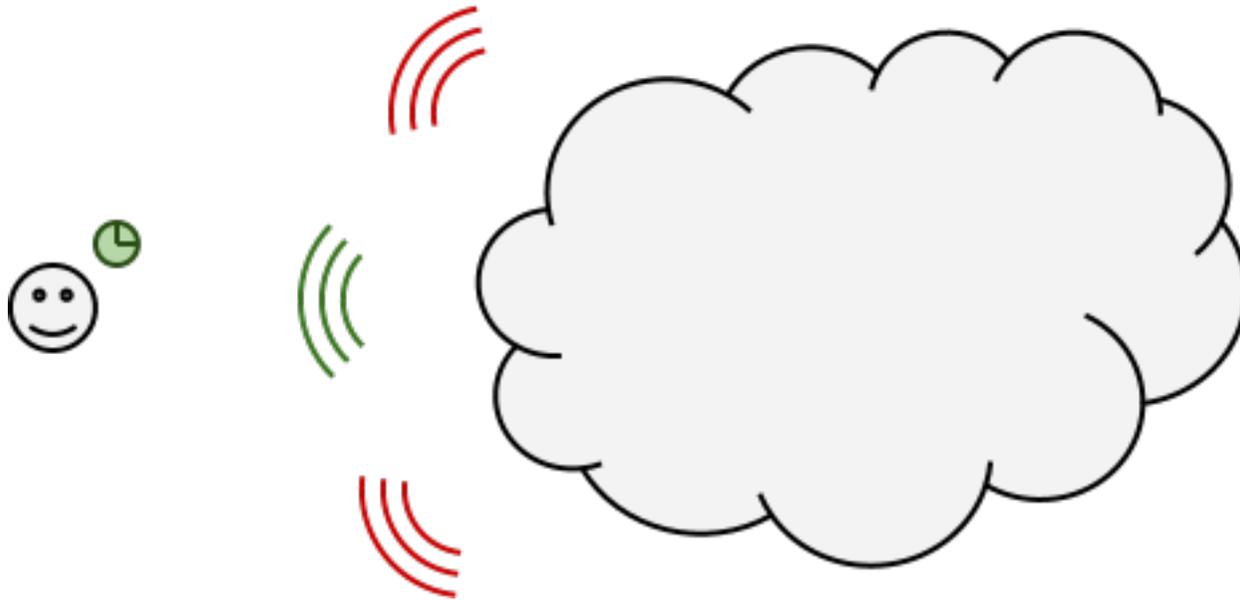

**Temporal diversity** by retry (**ACKs**) and failover mechanisms (**memorization of missing ACKs**).

# Joining a Network

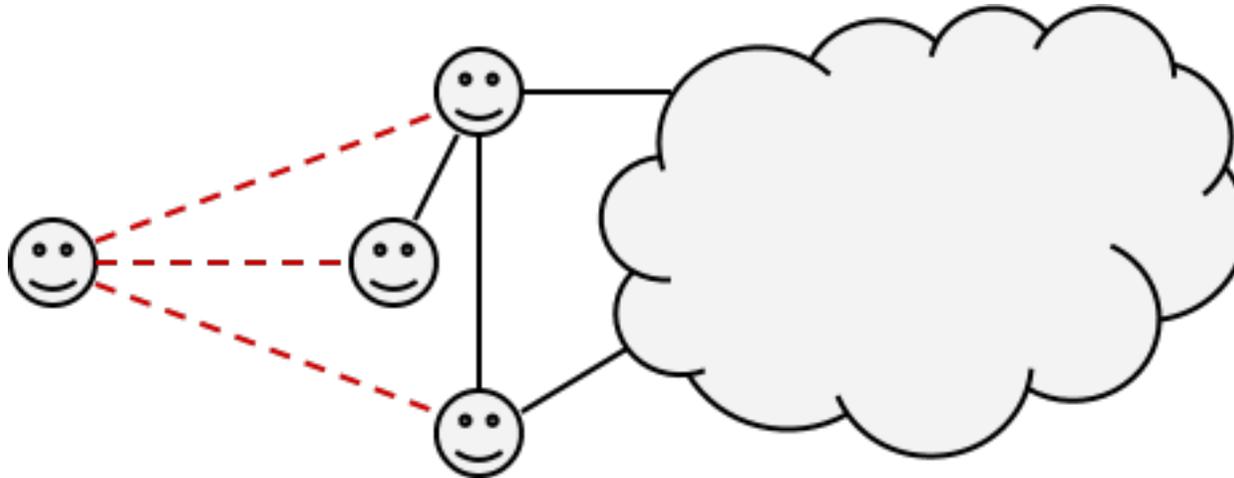

A node tries to join a network by scanning several frequencies, looking for some communication going on.

# Joining a Network

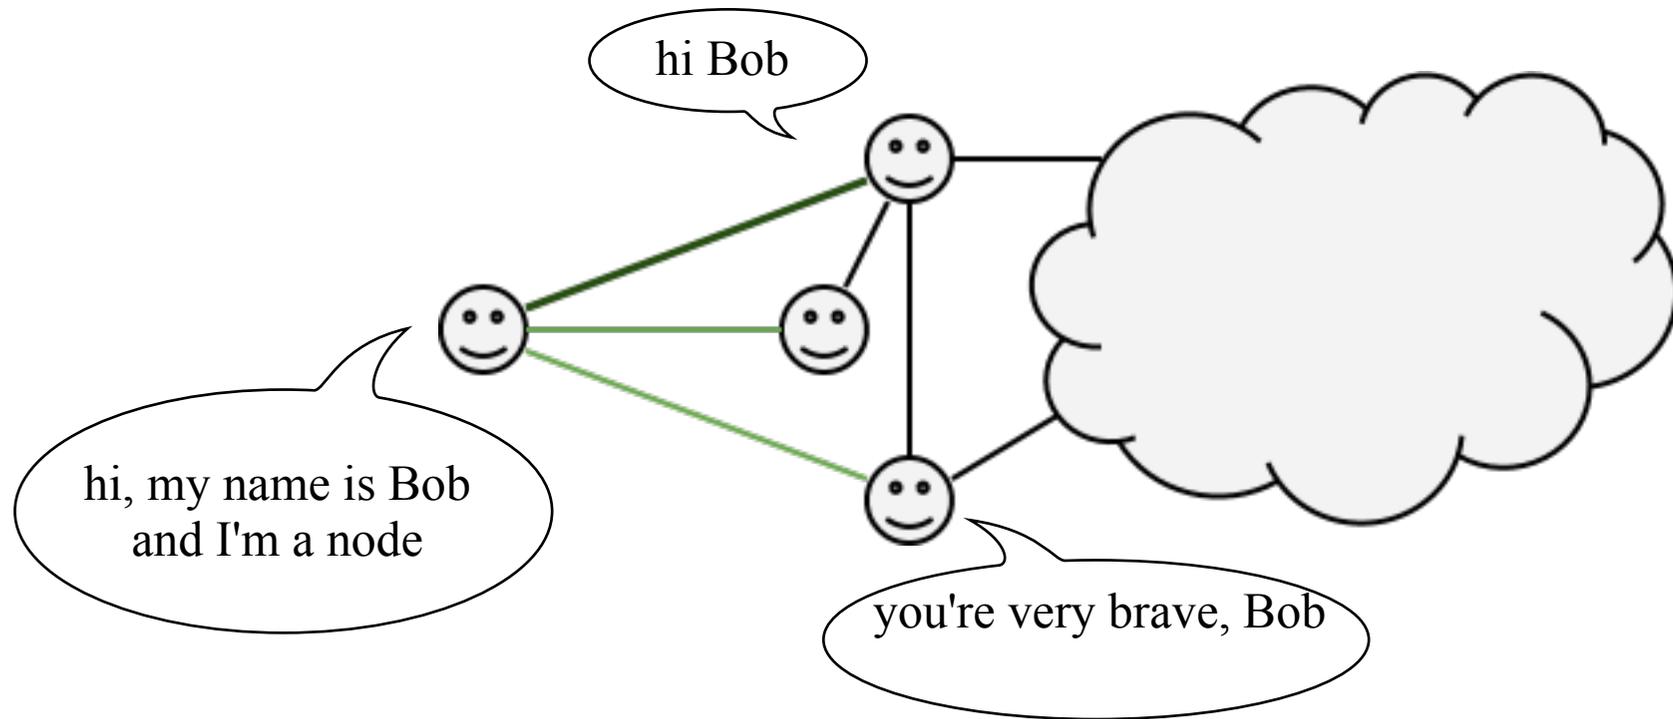

Once it listens to a **network advertisement**, it can **synchronize** with the network. Then, it continues the search for neighbors, but only using the time slots.

# Joining a Network

It builds a **neighbor list** and sends it in a **join request** to the network. Eventually, the manager will receive, evaluate and respond to it.

# Joining a Network

The manager assigns it some **links**, and after choosing its parent (s), it gets warmly welcomed in the group.

# Healing

**Periodic health reports** are sent to the manager and have statistics like

- MAC packets transmitted and failed,
- APP layer packets dropped,
- battery life, etc.

They provide the manager the right information for **graph modifications** and **efficient link management**.

# Network Modification

**Periodic neighbor discovery** allows TSMP to stay in constant evolution by taking advantage of the temporal changes that might happen in the network.

This provides **network optimization** as well as **repair**.

Might be turned off for energy saving purposes.

# Security

## The NET layer

- **encrypts** the application payload and
- **authenticates** the payload and NET header.

## The MAC layer

- **authenticates** the entire packet.

**Integrity** is guaranteed via both the NET and MAC MICs.

# Security

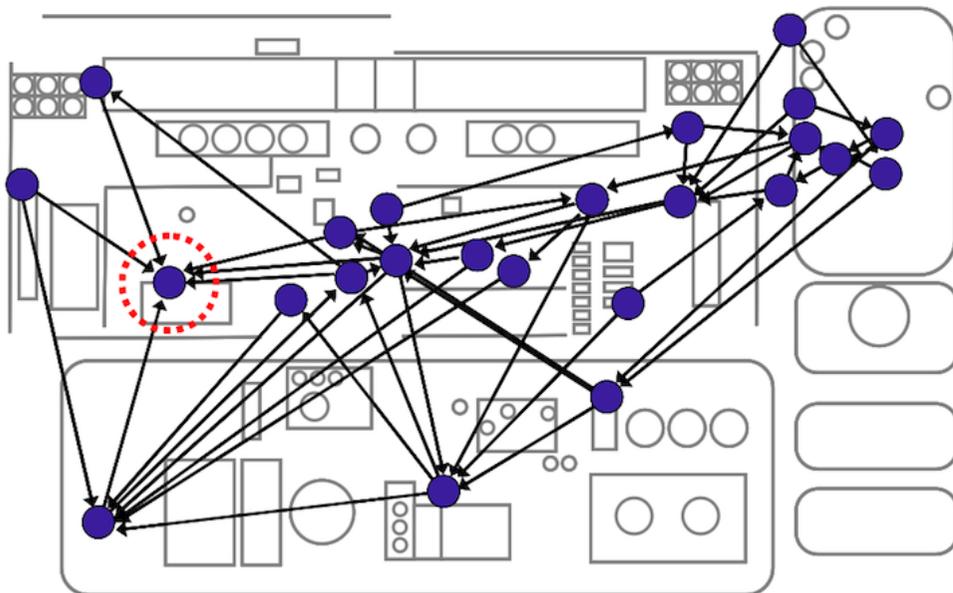

**Encryption** is a centralized security mechanism.

Every network has a pre-configured **Join Key**.

Upon joining a network with the right **Join Key**, and having been identified, a node is sent

- a **Session Key**, pseudo-randomly generated by the manager, used for **encryption**, and
- the **Network Key**, used for **authentication**.

# Results - Range

Network range over 400m

## Coker unit at oil refinery

- 24 nodes,
- no initial config,
- several hops of over 100m,
- installation performed by contractor.

**Reliability > 99.97% !**

# Results - Reliability

## Print shop

- 44 nodes,
- 3-floor, 15.000m<sup>2</sup> concrete and steel structure,
- environment heavily equipped with machines.

Measurements over 26 days recorded  
**17 out of 3.6 million packets lost!**

Even with occasional paths' stabilities  
going down to **null** for entire days.

# Conclusions

**Time sync** enables **better performance** in low-power networks than in an async fashion.

**Channel hopping** provides **higher stability and bandwidth**.

**Link allocation for graph routing** is the secret towards **flexibility**.

**Central management** can indeed provide commercially interesting deployments (up to hundreds of nodes).

**Thanks!**
