

# Principles of Distributed Computing

## Exercise 4

### 1 Shared Sum

In the lecture, we discussed how shared registers can be employed efficiently to allow each process to announce a value to all other processes. Now we look at a different scenario: Each process  $p_i$  computes a local variable  $x_i$  and we want to make the sum  $x := \sum_{i=1}^n x_i$  available to all processes.

We want to guarantee the following: If a process updates  $x_i$ , it should first ensure that  $x$  is updated accordingly before proceeding. However, we do not want to use a large number of registers or a huge register. In the following, you are given a single register which can store  $O(\log n)$  bits (the choice of the constant is up to you). Moreover, we assume that “ $x$  cannot become too large”, i.e., the  $x_i$  (and thus  $x$ ) are of size polynomial in  $n$  and hence can be encoded using  $O(\log n)$  bits.

- Give a solution using a shared register supporting the fetch-and-add operation with a constant update and access complexity. If possible, prevent both lockouts and deadlocks.
- Give a solution using a compare-and-swap register, also with constant access complexity. If successful, an update should need a constant number of steps (otherwise the process may retry). Are lockouts excluded?
- Give a solution using a load-link/store-conditional register. Compare it to the preceding solutions.
- Assume now that the return value of compare-and-swap is not whether the operation succeeded, but the value stored in the register after the operation. Can the problem still be solved? Prove your claim!

### 2 Space Efficient Binary Tree Algorithm\*

The adaptive collect algorithm using binary trees from the lecture requires to store a complete binary tree of depth  $n - 1$ , resulting in exponential memory requirements.

Suppose the algorithm is modified the following way: Whenever a process leaves a splitter with result **left** or **right** it flips a coin to replace this result by **left** or **right** with probability  $1/2$  each. Prove that for this randomized variant of the algorithm it is *with high probability*<sup>1</sup> sufficient to allocate memory polynomial in  $n$ .<sup>2</sup>

---

<sup>1</sup>I.e., with probability at least  $1 - 1/n^c$  for a choosable constant  $c > 0$ .

<sup>2</sup>Problems marked with an asterisk (\*) are hard. Example solutions to these problems will not be provided. However, anybody who solves such a problem will receive a prize!
